ABSTRACT

Optimizing Development Strategies to Increase Reserves in Unconventional Gas
Reservoirs. (August 2010)

Gulcan Turkarslan, B.S., Middle East Technical University

Chair of Advisory Committee: Dr. Duane McVay

The ever increasing energy demand brings about widespread interest to rapidly, profitably and efficiently develop unconventional resources, among which tight gas sands hold a significant portion. However, optimization of development strategies in tight gas fields is challenging, not only because of the wide range of depositional environments and large variability in reservoir properties, but also because the evaluation often has to deal with a multitude of wells, limited reservoir information, and time and budget constraints. Unfortunately, classical full-scale reservoir evaluation cannot be routinely employed by small- to medium-sized operators, given its time-consuming and expensive nature. In addition, the full-scale evaluation is generally built on deterministic principles and produces a single realization of the reservoir, despite the significant uncertainty faced by operators.

This work addresses the need for rapid and cost-efficient technologies to help operators determine optimal well spacing in highly uncertain and risky unconventional gas reservoirs. To achieve the research objectives, an integrated reservoir and decision modeling tool that fully incorporates uncertainty was developed. Monte Carlo simulation was used with a fast, approximate reservoir simulation model to match and predict production performance in unconventional gas reservoirs. Simulation results were then fit with decline curves to enable direct integration of the reservoir model into a Bayesian decision model. These integrated tools were applied to the tight gas assets of Unconventional Gas Resources Inc. in the Berland River area, Alberta, Canada.

DEDICATION

*in loving memory of my grandmother
Guzin Ekmekcioglu*

ACKNOWLEDGEMENTS

I would like to thank my committee chair, Dr. Duane McVay, for his guidance and support throughout the course of this research. Without his help, this work would not have been possible. I also would like to thank my committee members, Dr. Walter Ayers and Dr. Tom Blasingame, for their guidance and helpful comments.

Thanks also go to my friends whose existence made my stay at Texas A&M University a pleasurable and memorable one. I thank all of them and wish best of luck in their careers and studies.

I would like to especially thank my colleague, Mr. Tugrul Tas for sharing his extensive knowledge and experience on coding. In spite of the numerous logistical limitations, never once did he hesitate to offer his sincere help, for which I am truly grateful and deeply appreciate.

I owe my sincerest gratitude to my best friend, Dr. Murat Kaya Yapici, who has always been beside me whenever I needed his help. I am greatly indebted to him for his unwavering support, endless patience and generous help.

Lastly but most importantly, I would like to express my heartfelt gratitude to my beloved parents, Efser and Muharrem, and my dear sister, Ozlem for their unconditional love and support ever since. Without their encouragement, none of this would have been possible.

CHAPTER 1

INTRODUCTION

1.1 Statement and Significance of the Problem

The rapid growth in world energy demand and higher depletion rates of existing oil and gas reserves have initiated a gap between demand and supply (Zahid et al. 2007). To bridge this fast-growing energy gap and create a sustainable future energy supply, the global petroleum industry is investing heavily in exploration and development of unconventional energy sources.

During the 1980s, implementation of federal tax credits and various technical development programs in North America accelerated the development of new technologies for unconventional natural gas exploration and exploitation. With the advancement of technology, along with increasing gas prices, there has been growing interest in shales, tight sands and coalbed methane during the past decade (Xiong and Holditch 2006).

Among unconventional gas reservoirs in North America, tight sands hold the largest portion (Stark et al. 2007) and they represent an important source for future reserve growth and production. However, despite their tremendous reserve growth potential, tight gas reservoirs present significant technical and engineering challenges in characterization and exploitation, as well as uncertainties in production owing to complex heterogeneities and reservoir properties. Therefore, economic development of these assets remains risky.

Functioning within this risky domain, it is imperative that operators make sound judgements and development decisions such as determining the optimal well spacing. When making such decisions, one should conserve capital, protect the environment by avoiding over drilling and profitably maximize production by quickly achieving the optimal well spacing.

Examples of previous suboptimal development plans (McKinney et al. 2002) indicate potential losses of 50% in the asset value, which shows the importance of identifying the optimal well spacing early in the life of an unconventional gas field.

Traditionally, determination of the optimal well spacing has been carried out through statistical comparison of the performance of wells drilled at different spacings, from several infill programs with 10-40 year time spans. Unfortunately, for emerging tight sand plays, due to the lack of historical infill programs there is insufficient data to utilize traditional statistical comparison methods for evaluating optimal well spacing. Moreover, we do not have the luxury to develop these fields in an upcoming 40-year time span.

In summary, accelerating the development of unconventional gas reservoirs is critical to increase reserves and to meet the growing energy demand. Effective exploitation of these reservoirs can be achieved by developing fields at sufficiently dense well spacings, so that ultimate recovery is maximized while over drilling is avoided. Furthermore, the optimal well spacing must be reached early in the field's life to minimize capital expenditures and maximize profit.

1.2 Literature Review

Rapid and cost-effective assessments of optimal development strategies in marginal tight gas fields, such as well spacing and completion practices are critical to increase reserves and accelerate production, while protecting the environment. However, optimization of development strategies in tight gas fields is challenging, not only because of the complexity involved in the evaluation due to the wide range of depositional environments and large variability in reservoir properties, but also because the evaluation often has to deal with a multitude of wells, limited reservoir information, and time and budget constraints.

In recent years, the issue of determining optimal development strategies in tight gas fields has been followed with much interest in industry, and various authors have proposed techniques to address the challenges associated with geologic complexity of

these reservoirs and methods of handling large numbers of wells and limited reservoir information.

Newsham and Rushing (2001) introduced an integrated reservoir study including detailed geological, geophysical, petrophysical, reservoir engineering analyses and interpretations to evaluate infill drilling potential of a field and to determine optimal well placements. Unfortunately, such integrated studies cannot always be justified due to scarcity of data and marginal economics.

As an alternative to performing an integrated reservoir study for large, low-permeability gas reservoirs, some authors (Cipolla and Wood 1996; Guan and Du 2004; Guan and McVay 2004; Guan et al. 2002; Hudson et al. 2000; Hudson et al. 2001; Kyte and Meehan 1996; McCain et al. 1993; Voneiff and Cipolla 1996) proposed statistical moving window techniques to optimize the number and locations of wells to be drilled. While this technology can be a useful screening tool, the estimation errors for infill well performance can be quite significant as well interference effects become complicated and reservoir heterogeneity increases.

To improve upon moving window methods, some authors (Gao and McVay 2004; Cheng et al. 2006a; Cheng et al. 2006b; Cheng et al. 2008) suggested a simulation-based regression method combined with automated prediction to determine optimal well locations. The notable features of this method are (1) fast and cost-effective automatic history-matching and capability of handling hundreds of wells; (2) reliable reservoir characterization of large-scale heterogeneity for both permeability and pore volume and; (3) minimal data requirements.

In this section, we present an extensive survey of those approaches regarding the determination of optimal development strategies in marginal tight sand reservoirs.

1.2.1 Integrated Reservoir Studies

Optimizing the development of low-permeability gas reservoirs is most accurately done by conducting a full-scale reservoir evaluation involving geological, geophysical, petrophysical and reservoir engineering analyses and interpretations. This

includes developing a geological model of the field, approximating distributions of static reservoir properties such as porosity and permeability, building and calibrating an accurate reservoir simulation model of the study area and utilizing it for the estimation and optimization of reservoir development. Although, the reliability and accuracy of this approach is quite high, it is not always favorable due its time-consuming and expensive nature.

Rushing and Newsham (2001) presented an integrated work-flow process model to describe and characterize unconventional gas reservoirs. They modified and expanded the Petrophysical Integration Process Model (PPIM) of Gunter et al. (1997a, 1997b). The modified four-stage process model utilizes and integrates data from multiple and seemingly independent data sources; however, the key link among all data sources is the petrophysical model. Moreover, each stage of the process model both complements and supports other stages.

Stage 1 is a geological assessment that defines large-scale architecture and geometry of the reservoir from interpretations of structural geology, depositional environment and stratigraphy to obtain an estimate of the reservoir volume potential at deposition. Based on lithology and sedimentary structure, lithofacies are derived from core data, meanwhile well logs are used to identify vertical distributions of lithologies.

Pore-scale characterization of the rock and fluid systems are carried out in Stage 2 based on the geologic framework context that was previously defined in Stage 1. For pore-scale characterization, petrographic observations on pore structure, texture, mineralogy and diagenesis are made. As a result of this characterization, rocks are categorized into several hydraulic rock types depending primarily on their unique porosity-permeability relationships and capillary pressure characteristics.

Stage 3 is fundamentally an integration of the previously defined geological framework (Stage 1) and rock types (Stage 2) with formation evaluation techniques. This helps define reservoir flow units, seals and baffles which control fluid distribution and flow in the reservoir. For prediction of the vertical distribution of hydraulic rock types

along with their properties at each depth increment, petrophysical models formed on the basis of geophysical well log data are used.

In Stage 4, the geological and petrophysical models obtained in Stages 1-3 are calibrated with various reservoir models. The objective of this stage is to develop three-dimensional wellbore and reservoir flow models which can be employed in predicting future well performance and optimizing field development.

Reservoir models are defined as multi-well flow models incorporating both large-scale geological elements and small scale rock properties. Such models are useful for a variety of reasons. First, they provide a venue for optimizing well spacing through the analysis of production performance. Second, reservoir models could be used to evaluate targeted versus blanket infill drilling development practices. Third, they could serve as a means to quantify reserve growth in current production scenarios. Typically, reservoir models are classified into two as, stochastic and deterministic models.

Reservoir models that are built on principles of statistics and probability are termed as stochastic models. Such models use distributions to provide information on geological structures and rock properties, along with estimates on corresponding uncertainties on these distributions. Stochastic models have a variety of applications including the capturing of large-scale geological elements and small-scale petrophysical properties, as well as incorporating all reservoir heterogeneities. Other applications could be listed as, quantification of probable sand continuity between wells and determining rock property anisotropies and their distributions between wells. Usually, a large number of grids with small dimensions are used in constructing reservoir models, so that the range and sensitivity of the model is suitable for capturing variations at all scales. It is important to note that, stochastic models incorporate only static properties.

Deterministic models divide the reservoir into discrete grids; assign rock and fluid properties to each grid, and model vertical and horizontal fluid flow through the system. Since deterministic models employ larger grid blocks due to computational restrictions, properties from the finer-grid stochastic model are upscaled before being used in the coarse-grid deterministic models. Wellbore models; well stimulation

efficiencies in terms of fracture height, length, orientation, and conductivity; and hydrocarbon pore volume in pressure communication with the wellbore are also incorporated to the model. Major elements of a deterministic study include history matching field production, predicting future performance based on existing operating strategies and evaluating alternative operating and development strategies.

History matching is an inverse process that adjusts wellbore and reservoir parameters based on the historical production data. Once the model performance is matched to the actual production profile, future performance can be predicted for both existing and alternative development strategies.

Optimizing the development of low-permeability gas reservoirs is most accurately done by conducting a full-scale reservoir evaluation. This includes geological, geophysical, petrophysical and reservoir engineering studies, analyses and interpretations. Some key points in reservoir evaluation include, the development of a geological model of the field, approximating distributions of static reservoir properties such as porosity and permeability, developing and adjusting an accurate reservoir simulation model of the study area and utilizing it for the estimation and optimization of reservoir development. Although, the reliability and accuracy of this approach is quite high, it is not always favorable due its time-consuming and expensive nature.

1.2.3 Moving Window Method

As an alternative to conducting full-scale reservoir evaluations for large, low-permeability gas reservoirs having large data sets, some researchers (Guan and McVay 2004; Guan et al. 2002; Hudson et al. 2000; Hudson et al. 2001; Kyte and Meehan 1996; McCain et al. 1993; Voneiff and Cipolla 1996) conducted statistical moving window techniques to model variable well performance.

Essentially, the moving window techniques perform a statistical analysis of production data using defined performance indicators which serve as proxies for reservoir properties, production response and reservoir pressure. Based on the comparison of performance indicators between new and old wells within areal windows

throughout the study area, judgments are made concerning interference between existing wells, areas of depletion and undrained acreage. These judgments are then used to optimize the location of infill wells for maximum recovery and drainage of the reservoir with the fewest number of wells.

The moving domain technology incorporates a multitude of local analyses in areal windows each of equal size. The size of the window depends on the average spacing between data locations and on the dimensions of the study area. However, a margin of at least a few wells should be set within each window for a reliable calculation of summary statistics. When the number of wells in a window is less than a threshold value, then a regional or global regression is employed rather than a local regression, lowering prediction accuracy.

The major advantages of the moving domain technology over the integrated reservoir studies are its speed and its reliance on simply well locations and production profiles, which makes it a preferable screening tool for large infill development projects.

McCain et al. (1993) first introduced a statistical technique to determine the appropriate well density in complex, low-permeability gas reservoirs. This method is noteworthy, as it describes an objective way of comparing well performance, indicating regions that should be subjected to advanced analysis, and describing the areal locations where specific conclusions can be made.

Importance is given on making a clear and thorough geological and petrophysical description, and judging the coherence of reservoir descriptions established via independent geological and reservoir engineering methods.

This statistical technique is performed by building and analyzing graphs of well performance vs. date of first production. Well performance was characterized by the following productivity indicators: the maximum monthly production rate, the average monthly production rate for the best 12 consecutive months and the monthly production rate at the time a specific cumulative production was reached.

McCain et al. (1993) divided the entire field into equal sized study units. Each study unit included 10 to 20 wells. The three performance indicators of each study unit

were then plotted against the date of first production and a least-squares straight line was fitted to each of the data sets. Slope of the line fitted to the well performance data could serve as an indicator for interference between wells. More explicitly, a negative slope is interpreted as a sign of depletion at infill well locations due to overlapping well drainage areas, whereas a slope of zero indicates identically performing wells. Evaluating slopes of the least-squares lines on the performance indicator plots, areas of depleted infill locations were determined.

Voneiff and Cipolla (1996) improved the statistical method used by McCain et al. (1993) in their study on the Ozona field and named it “moving domain” technology. Basically, this technology appraises location and performance of existing wells to find evidence of depletion and to determine the optimal well spacing.

The moving domain technology described by Voneiff and Cipolla can be applied in two phases. The first phase is a scoping study provides the preliminary infill estimates, areas of depletion, and areas required for detailed conventional engineering. The second phase involves a more detailed engineering evaluation to calculate drainage areas, undrained acreage, recovery per acre, and infill reserves.

Guan et al. (2002) used a model-based analysis in each window. The model is based on a combination of the material-balance equation and the pseudosteady state flow equation, defined as,

$$\ln q = \ln(kh) + C_1 + \ln\left(p_i - p_{wf} - C_2 \frac{G_p}{A}\right) - \ln(\ln(\sqrt{A}) + C_3)$$

where

$$C_1 = -\ln(141.2\mu B)$$

$$C_2 = 0.00742 \frac{\pi B}{c_t h \phi}$$

$$C_3 = 0.40428 + s + 0.5 \ln(C_A r_w^2)$$

In generalized form,

$$y = a_0 + a_1 x_1 + a_2 x_2 + a_3 x_3$$

where

a_0 , a_1 , a_2 and a_3 are the regression coefficients that are assumed to be constant for a moving window.

$$y = \ln q$$

$$x_1 = \ln(kh)$$

$$x_2 = \ln\left(\frac{G_p}{A}\right)$$

$$x_3 = \ln(\ln(\sqrt{A}))$$

In this model, production rate (q), permeability-thickness product or reservoir quality (kh) and drainage area (A) are substituted by best year (BY), virgin best year (VBY) and well spacing, respectively. The moving window technology is based on this 4D regression model that correlates BY vs. VBY, cumulative withdrawal per acre and well spacing.

BY is simply the arithmetic average of the best 12 consecutive months of production, which often correlates well with long-term production. VBY is the BY of a well at virgin conditions and is determined by performing a 2D regression of BY vs. time. Well spacing is the area of voronoi polygon around each well based on x/y well locations.

The first step of the moving window technology is performing the 2D regression of BY vs. time to determine the VBY used in the subsequent 4D regression. The next step is regressing BY on VBY, cumulative withdrawal per acre and well spacing of wells within each window to determine the corresponding regression coefficients. Once the 4D regression equation is established for each window, performance of a candidate infill well in that window can be estimated.

Guan et al. (2002) provided a systematic assessment of the validity and accuracy of moving window technology in determining the optimum infill drilling strategy of low-permeability gas reservoirs. Performing a reservoir simulation study on an area of 100 producing wells from a field in Canada, they generated synthetic production data sets to be analyzed in the moving window technique. To examine the impact of

heterogeneity on prediction accuracy of this model-based statistical approach, they built 4 reservoir models with different degrees of heterogeneity but the same average permeability, 0.2 md. All the remaining parameters were kept the same for all cases.

To quantify the accuracy of moving window technology in assessment of VBY, which serves as a proxy for k_h in the 4D regression model, Guan et al. made a separate simulation run for each existing well in which they produced only that well for one year. Comparison of the VBY from the 2D regression to the VBY determined from simulation indicated that increased heterogeneity reduces the estimation accuracy. Accordingly, the best correlation was observed in the homogeneous reservoir model.

The next step was to determine the accuracy of moving window technology in predicting the infill well performance. This was achieved by placing in each grid block a new well that is produced for one year following the end of the performance history and generating the distribution of incremental production attributed to a new well at any possible location in the area. To convert the simulation-based infill well performance estimates from cell to well basis, a surrounding region on the simulation grid was attributed to each well. A well's region comprises all simulation cells closer to that well than to any other well. The arithmetic average of new well 1-year cumulative production, i.e. the infill BY, was then computed for each region and compared to the BY derived from the 4D regression model.

Comparison of infill BY from the moving window technology and reservoir simulation for different degrees of reservoir heterogeneity indicated that although estimates of infill well performance are mostly erroneous in individual well basis, the moving window technology predicts the average infill well performance well. Another conclusion that was reached from this analysis was that the moving window technology loses its effectiveness as the reservoir heterogeneity increases. The technique employed by Guan et al. (2002) is based on three assumptions:

The first assumption is that reservoir properties do not vary considerably within any moving window throughout the study area. As mentioned before, the reservoir model employed in this technique is established on a combination of the material

balance and pseudo-steady state flow equations, simplified by assuming that the reservoir is homogeneous within an individual moving window. The result is a 4D linear regression equation applied within each window. The second assumption is that completion and production techniques applied to each well are identical, regardless of when the well was drilled and completed.

Another assumption of the moving window technique is that at least a few wells in each part of the study area have reached the boundary-dominated flow, which may take several years of production for a tight gas well. This is required to compute drainage area and recovery per acre.

The analysis of moving domain technique in its entirety reveals three limitations of this method based on the three assumptions above.

While the first assumption is reasonable for most reservoirs, there also exist reservoirs that have rapid and dramatic change in their properties within a small area. For instance, some labyrinth-type reservoirs are comprised of narrow channel-fill bodies and substantial changes in rock properties may occur between sand units in jigsaw-puzzle reservoirs. In such cases, the estimations obtained by the use of moving domain technology may have errors and may not be reliable.

Another limitation of moving domain technology is that, in case the performance of the new wells are worse than prior ones, there is no clear indication of whether depletion or variation in rock properties have led to poor well performance. Moreover, various changes in completion and production technology over time could also suppress the effect of depletion.

The last limitation of this technique is the requirement that a certain number of wells exist in each part of the field, and that they display adequate production history to experience boundary-dominated flow. This condition is necessary for accurate calculation of the drainage area and recovery per acre. However, typically some low-permeability reservoirs require between 9 to 14 years to reach boundary-dominated flow. Therefore, moving window technology may not be applicable for some gas fields that have only short production profiles less than 10 years.

Despite these assumptions and limitations, this moving domain technique has been applied to the Ozona (Canyon) gas sands (Voneiff and Cipolla 1996), Milk River formation in Canada (Hudson et al. 2000), Cotton Valley in East Texas (Hudson et al. 2001; McCain et al. 1993), Mesaverde formation in the San Juan Basin (Hudson et al. 2001), and the Morrow formation in the Permian Basin (Hudson et al. 2001) to quantify infill potential.

1.2.4 Simulation-based Regression

To improve upon moving window methods, some authors (Cheng et al. 2006a; Cheng et al. 2006b; Cheng et al. 2008; Gao and McVay 2004) suggested combining conventional reservoir simulation with automated methods for assessment of infill potential in tight gas basins. Reservoir simulation inversion techniques aims to combine the greater accuracy of simulation-based methods with the short analysis times and low costs associated with statistical methods.

The simulation-based inversion technology developed by Gao and McVay (2004) differs from typical simulation inversion applications in that, rather than focusing on small-scale, high-resolution problems; it focuses on large-scale, coarse-resolution studies consisting of thousands of wells. This technique consists of two major components: forward modeling and inverse modeling.

The forward model used to calculate reservoir and well performance is a conventional 2D, single-phase, finite-difference gas reservoir simulator. This forward model is based on GasSim, a single-phase simulator for modeling real-gas flow in gas reservoirs. The main equations used in this simulator are,

(1) Real gas pseudo-pressure

$$p_p = 2 \int_0^p \frac{p}{z\mu} dp$$

(2) 2D flow equation

$$-a_N p_{pi,j-1}^{n+1} - a_W p_{pi-1,j}^{n+1} + a_C p_{pi,j}^{n+1} - a_E p_{pi+1,j}^{n+1} - a_S p_{pi,j+1}^{n+1} = d$$

where

$$a_C = a_N + a_W + a_E + a_S + \alpha$$

$$d = \alpha \cdot p_{pi,j}^n - q$$

$$\alpha = \frac{1}{\Delta t} \left(\frac{T_{sc}}{p_{sc} T} \right) \frac{\left(\frac{V_p P}{z} \right)_i^{n+1} - \left(\frac{V_p P}{z} \right)_i^n}{p_{pi}^{n+1} - p_{pi}^n}$$

(3) PI equation

$$q = J' (p_{pi,j}^{n+1} - p_{pwf})$$

where

$$J' = \frac{0.01988 k h T_{sc}}{p_{sc} T \left(\ln \frac{r_o}{r_w} + s \right)}$$

The reservoir simulator calculates individual well and field-wide production responses based on input static geologic model and other available reservoir data. However, since the initial geologic model is derived from static data only, it should be adjusted to the dynamic response of the reservoir through history matching.

Inverse modeling consists of an automatic history matching process that continuously adjusts reservoir properties until the best fit of calculated response to historical production data is achieved. The inversion of performance history is accomplished by sensitivity coefficient based algorithms, which requires the calculation of partial derivatives of production response variables with respect to reservoir parameters.

Gao and McVay (2004) employed the modified generalized pulse-spectrum technique (MGPST) for sensitivity calculation. Since the sensitivity coefficients obtained by partially differentiating the 2D flow equation with respect to gridblock permeability, they can be calculated internally by the simulator during a forward model run. Usually, sensitivity coefficients are calculated based on only those gridblocks with wells on production. This is mainly because of the availability of production data for

history matching being limited to gridblocks with wells and at time steps after wells start producing.

The procedure of simulation-based inversion is briefly described as follows: (1) run the forward model and calculate the sensitivity coefficients of production response; (2) perform inverse modeling to estimate the change in permeability required to honor production data and, update the permeability field correspondingly; and (3) assess infill drilling potential using forward modeling with the inverted permeability field.

Cheng et al. (2006a, 2006b, 2008) advanced the simulation-based regression approach by implementing a sequential inversion of both reservoir permeability and pore volume distributions. Adding pore volume to the regression enhances the quality of the history match, improves the resolution of reservoir characterization and lays a foundation for reliable prediction of future performance and assessment of infill drilling potential.

The sequential inversion of and infill assessment procedure is summarized briefly as follows: (1) run the forward model and compute the sensitivity coefficients of production response with respect to permeability; (2) perform inverse modeling to estimate the change in permeability required to honor production data and, update the permeability field accordingly; (3) run the forward model with the calibrated permeability field and determine the sensitivity coefficients of production response with respect to pore volume; (4) perform inverse modeling to estimate the change in pore volume required to honor production data and, update the pore volume field accordingly; (5) attempt to reach convergence between inversion on permeability and pore volume; (6) run several iterations until convergence between inversion on permeability and pore volume is reached and; (7) assess infill drilling potential using forward modeling with the inverted permeability and pore volume fields.

Later on, Cheng et al. (2006a, 2006b) improved this inversion algorithm by calculating porosity from the permeability-porosity correlation after the permeability field is calibrated and, then using the updated porosity field in the inversion of pore volume.

1.2.5 Limitations of Existing Methods

Among the existing methods, full-scale reservoir evaluation is the most accurate way to optimize development of unconventional gas reservoirs, but it is not routinely employed by small- to medium-sized operators given its time-consuming and expensive nature. On the other hand, while statistical moving-window and simulation-based regression techniques can provide rapid and cost-effective solutions, they employ deterministic principles and produce only a single representation of the reservoir. Hence, they do not account for uncertainties inherent in highly heterogeneous, complex reservoirs and quantify the risk involved in development decisions. Also, deterministic methods cannot model interdependencies present in tight gas reservoirs. Therefore, to model the production uncertainty and capture the impact of dependencies between parameters, a suitable approach would be to integrate stochastic and deterministic methods.

Given the considerable amount of uncertainty associated with unconventional resources, practical and flexible decision models are also needed to evaluate multiple development scenarios and hence, to assess the full spectrum of potential economic outcomes. Such models provide operators strategic insights for making profitable investment decisions in the face of significant risk.

Therefore, it is necessary to establish new methods which would allow assessment of optimal well spacing in a timely manner and also effectively manage uncertainties to achieve feasible development of unconventional reservoirs.

1.3 Objectives

The long-term objective of the overall project of which I am a part is to develop practical reservoir and decision modeling tools to help operators determine the optimal well spacing in highly uncertain and risky unconventional gas reservoirs as early in the reservoir life as possible. The technology and tools developed will be applied in UGR's tight gas assets in the Berland River area, Alberta.

The specific objective of this research work is to develop a fast, approximate, probabilistic reservoir model that assesses uncertainty in key reservoir parameters and allows prediction of production profiles as function of well spacing. Use of a probabilistic model will also provide a venue for modeling dependencies between parameters such as porosity, permeability and net pay. The reservoir model needs to be fast since it will be combined with a decision model and run thousands of times.

1.4 Organization of Thesis

This research focuses on the development and calibration of a probabilistic reservoir model for UGR's tight gas assets in Berland River area. Integration of this reservoir model with a Bayesian decision model will provide the basis for determining optimal well spacing for the area. The thesis is organized as follows:

Chapter I presents an overview of the problem, provides a review of literature on the subject and states the project goals. Chapter II gives a brief review of the general geology, depositional environments and stratigraphy of the Berland River area and the Gething Formation. Chapter III reports the tools and applications used in the construction of the probabilistic reservoir model, describes the reservoir simulation and Monte Carlo techniques that were employed, and explains different reservoir models established on different decision contexts. Chapter IV discusses the variogram analysis conducted to determine correlation coefficients between pairs of well porosities, net pay thicknesses and permeabilities, which were then incorporated into the reservoir model. Chapter V discusses the decline curve analysis performed on the simulated production profiles to facilitate the integration of the reservoir and decision models. Chapter VI briefly describes the decision model and presents the preliminary results. Chapter VII presents the conclusions, discusses the limitations of the study, and provides recommendations for future work.

CHAPTER II

GETHING RESERVOIR

The technology and tools developed in this project will be used to determine optimal well spacing strategies for Deep Basin tight gas sands in the Berland River area, Alberta. Unconventional Gas Resources Canada Operating, Inc. (UGR) is an active operator in the area, and is our industry collaborator.

In this chapter, a brief review of the general geology, depositional environments and stratigraphy of the study area are presented.

2.1 Background

The Berland River area is located on the edge of the Deep Basin of Western Alberta, Canada. Discovered in 1976, the Deep Basin of Alberta is considered as one of North America's giant gas fields with recoverable gas reserves ranging between 50 to 150 Tcf (Masters, 1979).

Fig. 1 shows the approximate location of the Berland River area. As with most tight gas fields, success depends upon identifying areas of good porosity and permeability, so-called sweetspots which are usually associated with coarse-grained sandstones and conglomerates (Smith et al. 1984).

The study area encompasses approximately 236 km² (58,240 acres and 91 sections) and includes about 120 wells. **Fig. 2** displays the Berland River base map in which regions outlined in blue show the sections where most of UGR's wells are located.

Fig. 3 depicts the stratigraphic view of the Berland River area. The various depositional environments are: 1) Cadomin - alluvial fan and plain, 2) Gething - fluvial deposits and flood plain, 3) Bluesky - shoreface sand and shales (Smith et al. 1984). The formation of interest in this study is the Gething.

Fig. 1—Location map showing the position of the study area relative to the Deep Basin of Alberta (Smith et al. 1984).

Fig. 3—Stratigraphic column of the Lower Cretaceous (Smith et al. 1984).

2.2 Gething Formation

The Gething formation consists primarily of interbedded fine- to medium-grained sandstones, siltstones, mudstones and coal sediments (**Fig. 4**). The sequence is terrestrial and is described as a low relief interior drainage plain on the eastern flank of the Cordillera.

Sandstones are fining upward or thin-bedded. Trough and planar cross-bedded, ripple-bedded and parallel-laminated sandstones are common. Plant material including fossil leaves, stems, logs, stumps, and other carbonaceous debris are also present.

Coalbeds exist throughout the Gething, and dinosaur foot prints have been discovered in Peace River.

Fig. 4—Type logs of the various facies of the Gething Formation (Smith et al. 1984).

The representative drainage pattern of the Gething sandstones is an active channel system that trended northeast at the time of deposition. With the burial of the

Fox Creek Escarpment by Gething sediments, there remained no local constraint on drainage which resulted in eastward expansion of the drainage plain. The physiography of this larger drainage system was a low-lying swampy plain with numerous shallow lakes and the area was heavily forested with conifers, cycads, and ferns. No evidence of marine sedimentation was observed in the study area although the coastline was not far away (Smith et al. 1984).

CHAPTER III

PROBABILISTIC RESERVOIR MODEL

The core of the technology developed in this work is a reservoir model that involves explicit modeling of subsurface uncertainty and an advanced decision model that fully incorporates uncertainty to optimally manage risk (**Fig. 5**).

Fig. 5 — Schematic illustration of the integrated reservoir and decision modeling tools

The reservoir model uses (1) reservoir simulation techniques and (2) conventional Monte Carlo methods to predict production profiles with a wide variety of reservoir properties and under different development scenarios; (3) geostatistical techniques to model dependencies in production response among wells and; (4) decline curve analysis to specify the decline parameters that best capture production profiles. To integrate all the different techniques used in constructing the reservoir model and automate the performing of thousands of simulations, a VBA code was developed. In this way, the reservoir model can provide a full spectrum of production profiles under different downspacing scenarios.

Once the reservoir model is established, it serves as a basis to construct a practical decision model. The decline parameters obtained from the decline curve model

will be inputs for the decision model which will yield estimates of the expected net profit under different scenarios. Hence, the model will allow operators to select the optimal development strategy with the objective of maximizing profitability.

In this project, two probabilistic reservoir models that allow for two development stages (a primary development stage followed by one stage of downspacing) were built for the modeling studies of UGR's tight gas assets in the Berland (Gething) reservoir. The first reservoir model is based on UGR's specific development strategy in the Berland River area. The second model follows a more general approach based on simulating a variety of downspacing combinations to evaluate different development scenarios.

In this chapter first the tools and applications used in the construction of the probabilistic reservoir model are reported. Then, the reservoir simulation and Monte Carlo techniques employed in the model are described and the input variables are presented. Finally, the two different models established on different decision contexts are discussed in detail.

3.1 Monte Carlo Probabilistic Approach

Most tight gas reservoirs are characterized by complex geological, geophysical and petrophysical properties and a high level of heterogeneity and hence, involve considerable uncertainty. Because of the large number of unknowns, a merely deterministic approach remains inadequate to quantify the range of variability in outcomes such as cumulative gas production or net present value and, therefore, to assess the risk associated with future performance predictions. Consequently, to model production uncertainties and quantify the risk involved in the development decisions, a suitable approach would be to integrate stochastic and deterministic methods.

To address these issues, a stochastic modeling tool, @Risk from Palisade Group is coupled to CMG's full featured simulator, IMEX from Computer Modeling Group so that thousands of simulations can be run to evaluate combinations of unknown parameters within their ranges of uncertainty.

A single-well, one-layer, single-phase reservoir model was built for the modeling studies of Berland River (Gething) reservoir. The reservoir simulator was formulated for the analysis of hydraulically fractured gas wells.

The Gething reservoir is a commingled, stratified multilayer system. In other words, there is no formation crossflow and vertical permeabilities of all layers are assumed to be zero. The flow capacity of such a system would be equal to the arithmetic sum of the flow capacities of all layers. Therefore, summing all the reservoir layers and representing them by a single simulation model layer will be a reasonable assumption.

A VBA code was generated in Excel to perform thousands of simulations automatically. An example input file to be run in IMEX was created and uncertain parameters were defined by @Risk distribution functions. **Fig. 6** is a block diagram representation of the applications and tools used in the construction of the Gething reservoir model.

The uncertain parameters and their associated distributions involved in modeling of Berland River (Gething) reservoir are presented in **Table 1**. The histograms and the corresponding probability distribution functions of these uncertain input variables obtained from a simulation of one thousand iterations are illustrated in **Fig. 7**.

Fig. 6— Block diagram representation of the applications and tools used in this study.

Table 1— Uncertain input variables involved in the modeling of Berland River (Gething) reservoir (data from UGR).

	Units	Distribution		Minimum	Maximum	Mean	Most Likely	Std dev.	Shift
		Type							
Net Pay	m	Log-normal	0.4	15	6.5	-	4.45	0.6	
Total Porosity	%	Normal	6	14	10.2	-	1.4	-	
Formation Depth	m	Normal	2600	3100	2780	-	91	-	
Drainage Area	acre	Triangular	40	640	-	160	-	-	

In addition to the parameters defined in Table 1, the average reservoir pressure is also uncertain since it is computed in the model by multiplying a constant pressure gradient with the formation depth which itself is an uncertain variable defined with a normal distribution.

Fig. 7— Histograms and probability distribution functions of uncertain input variables used in the modeling of Berland River area: (a) Net pay, (b) Porosity, (c) Formation depth, (d) Reservoir size.

The permeability model is based on a porosity-permeability relationship assumed to honor the heterogeneity and core data from the field. The correlation is given by,

$$k_{gas}(md) = 0.0071 * \exp(47.517 * \text{Gas Porosity})$$

A scalar factor of 1.92 was added to this correlation to calibrate the simulation model to the well performance data. Applying the scalar factor and rearranging,

$$k_{gas}(md) = 1.92 * \exp(47.517 * \text{Gas Porosity} + \ln 0.0071)$$

Uncertainty is incorporated into the permeability model as well, by assigning a normal distribution to the porosity-permeability correlation defined above. The expression inside the exponential function is assigned as the mean of this normal

distribution and a standard deviation of 0.55 is used (data from UGR). As expected, the generated synthetic permeability data set shows a log-normal distribution (**Fig. 8**).

Fig. 8— (a) Probability distribution plot (PDF), (b) cumulative distribution plot (CDF) of permeability.

Fig. 9 shows the permeability cloud which was obtained from a simulation of one thousand iterations based on the described porosity-permeability correlation. The red line is the regression line computed deterministically at 6% and 12% gas porosity. The permeability-porosity cloud is represented by the black dots, and the trendline shows the least-squares regression through the cloud data. The overlapping regression lines indicate an excellent match between deterministic and probabilistic models.

Fig. 9—Porosity-permeability cloud.

Reservoirs that originate in non-marine, channel (fluvial) environments such as the Berland River (Gething) reservoir are often characterized by laterally discontinuous sand bodies. The fluvial channel geometry is generally defined by its width/thickness (aspect) ratio. An aspect ratio of 7 was used in the modeling of the Berland River (Gething) reservoir.

The reservoir model depicts a quarter of the section; however, during simulation the thickness is multiplied by four and extended to cover the entire section. Representative gridblocks in one quarter of the model are drawn (**Fig. 10**) to show the positions of the gridblocks' centroids (centroid X and centroid Y) with respect to the well location, as well as the aspect ratio of the gridblocks. The model includes a hydraulic fracture near the wellbore, along the x-axis. To accurately model gas flow in the hydraulically fractured well, the hydraulic fracture is explicitly modeled by refined grids along the fracture and around the wellbore (Fig. 10).

Fig. 10—Gridblocks model based on an aspect ratio of 7: (a) Grid Centroid X, (b) Grid Centroid Y.

Other input parameters in the Berland River reservoir model are as follows; initial pore pressure gradient (0.28 psi/ft), water saturation (30%), reservoir temperature (90°C) and gas gravity (0.71). The hydraulic fracture has a length of 200 ft and an approximate width of 0.04 ft. The dimensionless fracture conductivity (F_{cD}) used in the model is 1.3 (**Table 2**).

The fracture permeability is computed as,

$$k_f (md) = \frac{F_{cD} * L_f * k}{w}$$

However, observing that an F_{cD} of 1.3 resulted in extremely high fracture conductivities for the higher permeability wells, wk_f was limited to a maximum value of 150 md-ft, which means that the fracture permeability, k_f cannot exceed 3750 md.

Table 2— Input parameters employed in the Berland River reservoir model (data from UGR).

	Units	Value
Pressure Gradient	psi/ft	0.28
Reservoir Temperature	°C	90
Aspect Ratio	-	7
Gas Gravity		0.71
Water Saturation	%	30
Fracture Length	ft	200
Fracture Width	ft	0.04
Dimensionless Fracture Conductivity	-	1.3

3.2 Reservoir Models for Different Decision Contexts

3.2.1 First Reservoir Model

The first reservoir model was established on UGR's specific development decision for the Berland River (Gething) reservoir. In our discussions, UGR stated their interest in developing some specific sections in the left region that is enclosed in blue in the base map (Fig. 2). The intention was to drill one well in those sections and then decide on whether to downspace or not, based on the first stage production results. UGR considered the drilling of up to 3 additional wells in the second stage.

The information provided by UGR and the base map of the Berland River area (Fig. 2) suggests that the study area is mainly developed on 320-acre spacing. Considering that there are already two wells in almost each section of the field, the reservoir model is built under the assumption that up to four more wells will be drilled in

a section. Among these, two will be in the same section as the existing wells, whereas the other two will be placed in neighboring sections (**Fig. 11**).

Fig. 11— Schematic illustration showing possible existing and new well locations.

The development decision modeled for the Gething reservoir is established on a two-stage downspacing with stage length of 1 year. In the first stage, a single well will be drilled in a section, which will increase the number of wells to three and reduce the well spacing to 213 acres in this section. As for the second stage, either no wells or up to three additional wells may be drilled. The first option is to continue production from existing wells, without including additional wells. The second option is to drill one new well, which marks the fourth well in that particular section, hence decreasing the well

spacing down to 160 acres. The third option is to drill two wells, one of them being in the section under consideration (fourth well in this particular section) and the other one in a neighboring section (third well in the neighboring section). The fourth option is similar to the third option except that one more well is drilled in another neighboring section (one well on 160 acre-spacing in the particular section, and two wells on 213 acre-spacing in two different neighboring sections).

The average reservoir pressure is computed in the model using a pressure gradient of 0.2 psi/ft which was reported in a reservoir characterization study of the Berland River area conducted by Schlumberger Data and Consulting Services, College Station, TX. This average reservoir pressure is designated as the initial pressure of the first stage. Since drainage interference is assumed to exist only within the same section, i.e., the section boundaries are assumed to be no-flow boundaries, the final pressure of the first well (Stage 1) is assigned as the initial pressure of the second well (Stage 2) while the reservoir pressure is assumed to be the initial pressure of the third and fourth wells (Stage 2).

Simulation results quantify best-month gas production, stage-end average pressure, stage-end gas production and the discounted cumulative production for each well. Table 3 display example simulation results of the first reservoir model for Option 1 where one well is drilled in Stage 1 and no additional wells are drilled in Stage 2.

Use of a reservoir simulation model with Monte Carlo techniques provided production estimations in forms of probabilistic distributions. **Fig. 12** depicts the probability distribution plot of the discounted cumulative gas production of Well 1 on 210 acre-spacing (Stage 1) which showed a log-normal distribution with a median of 497.5 MMscf. Probability distribution plots of other production data sets are presented in Appendix A.

Crossplots of Stage 1 vs. Stage 2 gas productions were generated to provide insights on dependencies between primary and secondary development plans. **Fig. 13** shows the crossplot of Stage 1 and Stage 2 gas productions for Option 2 where one well is producing in Stage 1 (Well 1) and one additional well (Well 2) is drilled in Stage 2. Remaining crossplots are included in Appendix B.

The statistics (mean and standard deviation) of each production data set and the pairwise correlation coefficients between Stage 1 and Stage 2 productions are displayed in **Table 4**.

The model described in this section was based on UGR's specific development decision, and is important in showing the capability of our technology in adjusting to different decision contexts.

Table 3— Example simulation results of the first reservoir model for Option 1 (One well is drilled in Stage 1 and no additional wells are drilled in Stage 2).

3.2.2 Second Reservoir Model

The second reservoir model follows a more general approach and analyzes all possible two-stage downspacing combinations to study the effect of downspacing in the Berland River area, and to determine the optimal development strategy for the asset. More specifically, the decision context to be modeled consists of two development decisions: the primary and secondary well spacings. The intention is to start development on a specific well spacing and then decide on whether to downspace or not, based on the primary production results. For this purpose, first a preliminary model was developed and the feasibility of the approach was tested. Later, the preliminary model was revised to provide a complete, final reservoir model. The following sections discuss these models in detail.

3.2.2.1 Preliminary Model

The decision context behind the preliminary version of the reservoir model was to start development on 640, 320 or 160 acre-spacings and then, to decide on the secondary well spacing based on the primary production results. Therefore, the model is built to evaluate all possible two-stage downspacing combinations between 640, 320 and 160 acres (**Table 5**). Four wells were modeled in a section and, depending on the downspacing alternative; the corresponding well(s) was/were simulated (**Fig. 14**). For instance, when downspacing from 640 acres (Stage 1) to 160 acres (Stage 2), 1 well is producing in Stage 1 and 3 more will be drilled in Stage 2. In this model, a fixed stage-length of 2 years is used. Hence, Well 1 will produce for 2 years after which Wells 2 through 4 will be drilled, and all will produce for another 2 years.

To account for variability in reservoir properties at different well locations, all wells are modeled individually, but sampled from the same probabilistic distributions. In other words, the reservoir heterogeneity is modeled to a certain extent although a single-well model is used. Spatial dependencies in reservoir properties are also modeled and incorporated into the reservoir model.

Table 5—Possible downspacing combinations evaluated in the preliminary reservoir model.

Stage 1 \ Stage 2	640	320	160
640	X		
320	X	X	
160	X	X	X

Fig. 14— Possible two-stage downspacing combinations. Numbers on top of arrows indicate Stage 1 wells and additional Stage 2 wells.

The average reservoir pressure is computed using the initial pore pressure gradient specified as 0.2 psi/ft by UGR and is assigned as the initial pressure of the first-stage wells. On the other hand, based on an initial assumption that drainage interference is likely to exist throughout the section, the average pressure at the end of first stage is assigned as the initial pressure of second-stage wells.

Once the reservoir model was established, a reservoir simulation of one thousand iterations was conducted to quantify best-month gas production, stage-end average pressure and stage-end gas production for each well (**Table 6**).

Table 6— Example simulation results of the preliminary reservoir model. In Stage 1, one well (Well 1) is producing on 640 acre-spacing. In Stage 2, an additional well is drilled (Well 2) on 320 acre-spacing.

To test and validate this simple, preliminary model, simulated best-month and 24-month productions were compared with actual field data. Comparison was made for simulated cases which include 2 wells, since the study area is mainly developed on 320-acre spacing (**Fig. 15**).

Fig. 15— Simulated cases used in the comparison. Wells labeled in red are compared with the actual field data.

Fig. 16 shows the cumulative distribution plots of the best-month and 24-month gas productions. The production distributions estimated by the reservoir model closely match the actual production distributions, which confirm the feasibility of the approach. Following the development and verification of the preliminary model, a more advanced, final model was developed which will be discussed in the next section.

Fig. 17 depicts the probability distribution plot of the stage-end gas production of Well 1 on 640 acre-spacing (Stage 1) which showed a log-normal distribution with a median of 515 MMscf. Probability distribution plots of other production data sets are presented in Appendix C.

We also generated crossplots of Stage 1 vs. Stage 2 gas productions to illustrate the dependency of Stage 2 on Stage 1 (Appendix D). **Fig. 18** shows an example where

first and second stage productions of Well 1 on 640 acres are plotted against each other. Stage 2 exhibits strong dependence on Stage 1 with a correlation coefficient of 0.894.

Fig. 16— Cumulative distribution plots of (a) best-month gas production and (b) stage gas production.

Table 7 displays the statistics (mean and standard deviation) of each production data set and the pairwise correlation coefficients between Stage 1 and Stage 2 productions.

Fig. 17— Probability distribution plot of stage-end average gas production for Well 1 on 640 acre-spacing (Stage 1).

Fig. 18— Crossplot of Stage 1 (640 acres) vs. Stage 2 (640 acres) gas productions.

3.2.2.2 Final Model

This model follows the same approach used to develop the preliminary model, but with two major improvements. First, the downspacing alternatives also include 80-acre spacing, allowing more development scenarios to be evaluated (**Table 8**). Second, production is forecasted over a total period of 20 years and each well's production profile is estimated.

Table 8—Possible downspacing combinations evaluated in the final reservoir model.

Stage 2 Stage 1	640	320	160	80
640	X			
320	X	X		
160	X	X	X	
80	X	X	X	X

This final version of the reservoir model is established assuming the drilling of up to 8 wells in a section (**Fig. 19a**). The wells are numbered according to the drilling sequence to be followed during development of Berland River area. For simplicity and shorter computation times, only four of the eight wells (**Fig. 19b**) are modeled.

Wells 1 through 4 are assigned to well spacings of 640, 320, 160 and 80 acres, respectively. For each downspacing combination, only one well is used to represent all the wells that will be drilled at each stage (**Fig. 20**). For instance, when downspacing from 320 acres (Stage 1) to 80 acres (Stage 2), 2 wells are producing in Stage 1 and 6 more will be drilled in Stage 2. In this case, Well 2 and Well 4 will be simulated to represent all Stage 1 and Stage 2 wells, respectively.

Although a single-well model is used in the reservoir characterization of the Gething Formation, the heterogeneity is modeled by attributing different reservoir properties to each well. That is, each well were modeled individually but sampled from the same statistical distributions.

Fig. 19— Schematic illustration showing (a) possible well locations, (b) representative well locations.

Fig. 20— Possible two-stage downspacing combinations. Numbers on top of arrows indicate Stage 1 wells and additional Stage 2 wells. Wells 1 through 4 are the representative wells.

At first, the average reservoir pressure was assigned as the initial pressure of first-stage wells, whereas the initial pressure of second-stage wells were modeled probabilistically on the rough assumption that there may be 75% chance of communication (i.e., pressure interference) between the second- and first-stage wells, and 25% chance of no communication. This assumption was made based on a quick analysis of Berland River permeability maps, which reveal drainage interference roughly in three forth of the study area.

To establish the probabilistic pressure model, a uniform distribution that generates random numbers between 0 and 1 was assigned for each well to represent its likelihood of having pressure interference with the adjacent wells. If the random number generated for a well by its @Risk uniform distribution function is lower than 0.25, the average reservoir pressure is designated as the initial pressure of this particular well; otherwise, the final pressure of the first stage- well(s) is/are assigned as the initial pressure of the same well.

However, in reality pressure interference between first- and second-stage wells depends on the well spacing, i.e., number of wells drilled in a section and areas that are being drained by these wells. Therefore, one would expect a greater chance of communication between wells when the field is developed on a smaller spacing. In other words, as more wells are drilled, the probability of pressure interference increases. Also, the greater the reservoir size of each well, the higher the chance of communication between adjacent wells.

Thus, to illustrate the effect of well spacing and drainage area on production interference, different probabilities representing pressure interference were assigned for each production scenario based upon well spacing and reservoir size of the first-and second-stage well/wells.

Completion efficiency of Berland River (Gething) wells was also modeled probabilistically. Based on information provided by UGR, a failure rate of 10% was assumed and incorporated into the reservoir model. To do so, a uniform distribution that generates random numbers between 0 and 1 is assigned for each well to represent its likelihood of having stimulation failure. If the random number generated for a well by its @Risk uniform distribution function is lower than 0.1, meaning that the fracture treatment failed, the fracture conductivity, k_f is equal to the permeability; otherwise, it is defined by the following equation; $k_f(md) = \frac{F_{cD} * L_f * k}{w}$ where F_{cD} is fixed at 1.3 and k_f cannot exceed 3750 md.

Once established, the reservoir model was run with 1-, 3- and 5-year stages to understand the trade-off between Stage 1 spacing and duration and illustrate how the value of learning about the primary development plan varies with stage length. **Tables 9 through 11** show example simulation results of the model for stage-lengths of 1, 3 and 5 years, respectively.

The remaining chapters (Chapter IV - correlation coefficients, Chapter V - decline curve model, Chapter VI - decision model) will all be based on the final reservoir model that was presented in this section.

Table 9— Example simulation results of the final reservoir model for a stage-length of 1 year. In Stage 1, one well (Well 1) is producing on 640 acre-spacing. In Stage 2, three additional wells are drilled on 160 acre-spacing and represented by Well 3 in simulation.

CHAPTER IV

CORRELATION COEFFICIENTS

The motivation of this study was to build a reservoir model using fast simulation techniques paired with stochastic methods to provide production profiles within a wide range of reservoir properties and under multiple development scenarios. Stochastic methods include Monte Carlo simulation to quantify uncertainty in reservoir properties in forms of probabilistic distributions and geostatistical analysis to honor spatial variations of these reservoir properties within the reservoir.

Previous chapters discuss the reservoir characterization study of the Gething formation where statistical distributions are attributed to uncertain parameters for a subsequent Monte Carlo simulation, and also present the stepwise development of the probabilistic reservoir model.

In this chapter, the geostatistical analysis performed to provide spatial distribution of the reservoir properties is presented and the correlation coefficients incorporated to the reservoir model are reported.

Since spatial variations of reservoir properties in the Gething tight gas formation are considered to determine dependencies in production response between wells for decision modeling, dependencies in reservoir properties were identified based on a geostatistical study performed by Schlumberger Data and Consulting Services, College Station, TX. A variogram analysis was conducted and, based on interwell distances, the correlation coefficients for porosity, permeability and net pay were computed, which were then incorporated into the probabilistic reservoir model.

4.1 Variogram Analysis

Variograms are the most widely used tools in geostatistics to investigate spatial variability of lithofacies and petrophysical properties. Building variograms in a particular direction provides insight in determining spatial distribution of some reservoir parameters such as porosity and permeability in that direction. A display that quickly

reveals directional anisotropies is a contour map of the sample variogram surface. Contour maps may serve as useful means of establishing the minimum and maximum continuity directions (Isaaks and Srivastava, 1989).

A variogram analysis was performed for Berland River area to generate possible representations of porosity, permeability and net pay at interwell locations and determine the correlation coefficients between wells separated by specific distances. Then, examining the variogram maps created for the Gething D formation, the major and minor directions of continuity were determined and the corresponding variograms are plotted.

Fitting a variogram model to each of these reservoir properties, the theoretical variograms were reproduced in an Excel spreadsheet for both major and minor directions of continuity. These theoretical variograms were plotted with their associated covariance and correlation functions.

Porosity map and porosity variogram map of the Gething reservoir are shown in **Fig. 21** and **Fig. 22a**, respectively. Based on the variogram map, the major and minor continuity directions for porosity are determined as 68° and 338° . The corresponding major and minor direction empirical variograms and the theoretical models fitted to these experimental variograms are shown in **Figs. 22b and 22c**. These empirical variograms are of exponential type with a sill of 1.055 and nugget of 0.034. The major range is established as 3913 m and the minor range as 2015 m.

Fitting an exponential model to the empirical porosity variograms, the theoretical variograms are generated for both major and minor directions of continuity, along with their associated covariance and correlation functions (**Figs. 22d and 22e**). For the exponential variogram which is a commonly used transition model, the following standardized equation is used:

$$\gamma(h) = C_0 + C_1 \left[1 - \exp\left(-\frac{3h}{a}\right) \right]$$

where $\gamma(h)$ is the semi-variogram, C_0 is the nugget which provides discontinuity at the origin, C_1 is the difference between sill (or covariance at 0 separation distance, $C(0)$)

and nugget, a is the range providing a distance beyond which the variogram remains essentially constant and h is the separation or lag distance between pairs.

To compute the covariance function of porosity represented in red in Figs. 22d and 22e, the relationship between variogram and covariance expressed as $C(h) = C(0) - \gamma(h)$ is utilized. On the other hand, the correlation functions shown in yellow in Figs. 22d and 22e are derived from the covariance function using the formula $\rho(h) = \frac{C(h)}{C(0)}$.

Fig. 21—Porosity map of the Gething reservoir (provided by Schlumberger Consulting Services on Berland River area).

Fig. 22—Variogram analysis for porosity: (a) Variogram map (distances are in meters), (b) major and (c) minor direction empirical variograms, (d) major and (e) minor direction theoretical variograms with covariance and correlation functions (provided by Schlumberger Consulting Services on Berland River area).

Net pay map and net pay variogram map of the Gething reservoir are shown in **Fig. 23** and **Fig. 24a**, respectively. According to the variogram map, the major and minor continuity directions for net pay are noted as 297° and 207° . The corresponding major and minor direction empirical variograms and the theoretical models fitted to these experimental variograms are shown in **Figs. 24b and 24c**. These experimental variograms are Gaussian with a sill of 0.952 and nugget of 0.116. The major range is established as 2570 m and the minor range as 2470 m. The relationship between variogram and covariance is used to compute the covariance function which is then employed to derive the correlation function.

Fig. 23—Net pay map of the Gething reservoir (provided by Schlumberger Consulting Services on Berland River area).

Fig. 24—Variogram analysis for net pay: (a) Variogram map (distances are in meters), (b) major and (c) minor direction empirical variograms, (d) major and (e) minor direction theoretical variograms with covariance and correlation functions (provided by Schlumberger Consulting Services on Berland River area).

Permeability-thickness map and permeability variogram map of the Gething reservoir are shown in **Fig. 25** and **Fig. 26a**, respectively. Based on this variogram map, the major and minor continuity directions for permeability are established as 264° and 174°. The associated major and minor direction empirical variograms and the theoretical models fitted to these experimental variograms are shown in **Figs. 26b and 26c**. These empirical variograms are of spherical type with a sill of 0.997 and a zero nugget. The major range is determined as 2520 m and the minor range as 2430 m.

A spherical model is fitted to the empirical major and minor direction variogram estimates of permeability and theoretical variograms are generated along with their associated covariance and correlation functions (**Figs. 26d and 26e**). The spherical variogram functions are computed based on the following standardized equation:

$$\gamma(h) = C_0 + C \left[1.5 \frac{h}{a} - 0.5 \left(\frac{h}{a} \right)^3 \right]$$

Fig. 25—Permeability-thickness map of the Gething reservoir (provided by Schlumberger Consulting Services on Berland River area).

Fig. 26—Variogram analysis for permeability: (a) Variogram map (distances are in meters), (b) major and (c) minor direction empirical variograms, (d) major and (e) minor direction theoretical variograms with covariance and correlation functions (provided by Schlumberger Consulting Services on Berland River area).

Once the theoretical variograms are built, the corresponding covariance and correlation functions are computed based on aforementioned variogram-covariance and correlation-covariance relationships.

4.2 Correlation Coefficients

A variogram analysis is conducted to assess the spatial variations of reservoir properties within the Gething formation. Theoretical variogram, covariance and correlation functions are established for major and minor directions of continuity. Correlation functions are utilized to compute the correlation coefficients for porosity, permeability and net pay based on the planned well locations in a section.

As discussed in Chapter III, while the Gething reservoir model is built based on the assumption that at most 8 wells will be drilled in a section, only 4 of those are modeled. **Fig. 27** is a schematic illustration of the described well configuration with the 4 representative wells and the separation distances between them.

Fig. 27— Schematic illustration showing the representative well locations and the corresponding interwell distances in meters.

Tables 12 through 14 present the correlation matrices which display the correlation coefficients between all pairs of well porosities, net pay thicknesses and permeabilities. These correlation coefficients are later incorporated to the reservoir model to account for dependencies in reservoir properties between wells.

CHAPTER V

DECLINE CURVE MODEL

Reservoir simulation combined with Monte Carlo techniques provided a practical and quick method to predict a multitude of production profiles with various reservoir properties, under different development scenarios. These production profiles will be incorporated to a flexible decision model and allow calculation of the expected net present value for each scenario which will be used as a means to decide on the optimal development strategy. To facilitate the integration of the reservoir and decision models, simulated production profiles are fit with decline curves. The regressed decline parameters are then used in the decision model along with their means, standard deviations and pairwise correlation coefficients to specify a joint probability distribution for each development scenario.

This chapter provides background information on conventional decline curve analysis and describes the methodology followed in constructing the decline curve model in this work.

5.1 Background

Decline curve analysis is one of the most widely used techniques to predict future production performance and estimate reserves from available production data in conventional reservoirs. This technique is based on the assumption that the past production trend can be mathematically described by so-called Arps' rate-time equations and utilized to forecast future performance. Decline curve analysis may serve as an effective and powerful tool for reserve estimation and economic evaluation of an asset if applied under the appropriate conditions (Cheng et al. 2008).

Conventional decline curve analysis applies to cases in which there is a single-layer reservoir where the transient flow has died out and the well production is maintained at steady-state flow conditions with constant bottomhole pressure. It is important that the decline curve analysis is performed only after boundary-dominated

flow conditions are reached, that is when the change of reservoir pressure with time (dP/dt) is constant at all points for constant rate production. If the analysis were to be performed during transient flow conditions, predictions on future well performance would be inaccurate and misleading; since the effective drainage area of the well increases during this flow regime. Also there should not be any changes in completions. Under these conditions the Arps' equations can be effectively used for decline curve analysis (Cheng et al., 2008).

The three types of rate-time decline curves are (1) exponential decline, (2) hyperbolic decline and (3) harmonic decline. Detailed explanation on the first two methods will be provided next, whereas the last method will be omitted as it is beyond the scope of this work.

5.1.1 Exponential Decline Curve

Exponential decline which is also referred as constant percentage decline is the most commonly used Arps' model defined by an exponential equation of the form $y = ae^{bx}$. The equations used to interpret exponential decline curves are,

(1) Production rate at time t ,

$$q = q_i e^{-Dt}$$

(2) Cumulative production,

$$N_p = \frac{q_i - q}{D}$$

where the decline rate, D is expressed as,

$$D = \frac{\ln\left(\frac{q_i}{q}\right)}{t}$$

The rate-time equation governing exponential decline includes two constants which are the initial production rate, q_i and the decline rate, D . The decline rate is the rate of change in production with respect to time and, for exponential decline, is constant for all time (Fattah 2006).

5.1.2 Hyperbolic Decline Curve

Hyperbolic decline occurs when the decline rate varies with producing time. The equations that define hyperbolic decline curves are,

(1) Production rate at time t ,

$$q = q_i (1 + b D_i t)^{-1/b}$$

(2) Cumulative production,

$$N_p = \frac{q_i^b}{D_i(1-b)} (q_i^{1-b} - q^{1-b})$$

The rate-time equation defining hyperbolic decline incorporates three constants, the initial production rate, q_i the initial decline rate, D_i , which is defined at the same time as the initial production rate, and the hyperbolic exponent, b . The decline rate is no longer constant, but varies with time. The hyperbolic exponent is the rate of change of the decline rate with respect to time, or the second derivative of production rate with respect to time.

The hyperbolic decline model often results in unrealistically high reserve estimates and a long lifetime since the curve continually flattens with time. In contrast, the exponential decline model yields more conservative reserve estimates and predicts a relatively rapid depletion compared to the hyperbolic decline model (Fattah, 2006).

5.2 Applied Methodology

Conventional practices of decline curve analysis in tight gas reservoirs pose significant technical challenges and may often result in unrealistic production forecasts and inaccurate reserve estimates (Cheng et al., 2008). It is typical for tight gas reservoirs to have production performances with rapid initial decline rates and lengthy transition flow periods. In our model, to account for long-duration transient effects inherent in tight gas reservoirs, the early production data are matched with a hyperbolic decline which later assumes an exponential form. Equations for the combined hyperbolic and exponential production decline used in our model are derived as,

(1) Hyperbolic Decline Segment

The production rate at time t can be expressed as,

$$q = q_i (1 + bD_i t)^{-1/b}$$

The cumulative production,

$$N_p = \frac{q_i^b}{D_i(1-b)} (q_i^{1-b} - q^{1-b})$$

(2) Exponential Decline Segment

The initial exponential production rate may be obtained by substituting t_o in the rate-time equation describing the hyperbolic decline,

$$q = q_i (1 + bD_i t_o)^{-1/b}$$

The exponential decline rate, D , which will be constant during the exponential decline segment can be determined by,

$$D = \frac{D_i}{1 + bD_i t_o}$$

A production rate in the exponential decline segment can be expressed as:

$$q = q_i (1 + bD_i t_o)^{-1/b} \exp \left[\frac{-D_i(t - t_o)}{1 + bD_i t_o} \right]$$

The cumulative production,

$$N_p = \frac{q_i (1 + bD_i t_o)^{-1/b} - q}{\frac{D_i}{1 + bD_i t_o}}$$

Based on these equations and with the help of the Solver add-in of Excel, production profiles are matched with a decline curve. A VBA code automates the decline curve analysis of thousands of production profiles generated by random simulation runs of the reservoir model. The early production data during Stage 1 is acquired on a monthly basis and matched with a hyperbolic model; whereas, the rest of the performance history is collected on a yearly basis and matched using a hyperbolic decline that becomes exponential once boundary effects are felt (**Fig. 28**).

Fig. 28— Example of a simulated production profile from the reservoir model with 3-year stage length: (a) Hyperbolic decline model fitted to the first 3 years of production (b) An early hyperbolic model transitioning to exponential, fitted to the 20 years of production.

Decline parameters of Stage 1 (initial production rate q_i , initial decline rate D_i , and hyperbolic exponent b) and Stage 2 (q_i, D_i, b and transition time t_o) are determined along with their pairwise correlation coefficients to serve as inputs to the decision model.

5.3 Results of Decline Curve Model

As previously mentioned, the reservoir model was run with 1-, 3- and 5-year stages to illustrate how the value of learning about the primary development plan varies with stage length. **Tables 15 through 17** show example decline curve results for stage-lengths of 1, 3 and 5 years, respectively while **Tables 18 through 29** present the important statistics of decline parameters (mean and standard deviation) and pairwise correlation coefficients between Stage 1 and Stage 2.

These statistics (means, standard deviations and correlation coefficients) are input into the decision model. The decision model processes these inputs and yields the optimal development strategy.

The preliminary decision model that will be outlined in the following chapter only uses the initial production rate, q_i in the analysis. **Fig. 29** shows the cumulative distribution plots of the first well's 1 year- and 20 year- q_i s (stage length is 1 year). The remaining CDF plots are provided in Appendix E.

Table 17— Example decline curve results of the final reservoir model for a stage length of 5 years. In Stage 1, one well (Well 1) is producing on 640 acre-spacing. In Stage 2, three additional wells are drilled on 160 acre-spacing and represented by Well 3 in simulation.

CHAPTER VI

DECISION MODEL

The research team led by Dr. Eric Bickel (Industrial & Systems Engineering Department in University of Texas at Austin, UT) developed a practical and flexible decision model to evaluate a variety of two-stage development scenarios and assess the full spectrum of potential economic outcomes.

The model follows a practical approach for capturing the dependence between these stages and determines an optimal strategy that exploits the information provided by primary stage production results from the reservoir simulation. Production results are integrated to the decision model using the decline curve analysis approach described in the previous chapter (**Fig. 30**).

To fully model dependence between primary and secondary development plans, joint probability distributions of the decline parameters are constructed from a set of pairwise probability and correlation assessments. These distributions are then used to calculate the expected net present value which will form the basis of our decision.

Fig. 30— Schematic outlining the approach used in the decision model. Production profiles from the reservoir simulation are input into the decline curve analysis to generate the decline parameters. Means, standard deviations and correlation coefficients of the decline parameters are then calculated and input into the decision model. The decision model processes these inputs and yields the optimal development strategy.

This chapter briefly describes the decision model employed in this work and provides the results obtained from the model. The preliminary decision model that will be outlined in the following section only uses the initial production rate, q_i in the analysis and evaluates only the 1-year and 3-year results.

6.1 Methodology

When making sequential development decisions, one needs to capture the dependence between stages and use the primary production results to make more informed decisions for the next stages. **Fig. 31** shows the influence diagram for the decision on the development plan of the Berland River area. The net present value (NPV) is the objective variable, i.e., the quantitative criterion that will be maximized. In other words, the decision model selects the optimal development strategy with the objective of maximizing profitability. The optimal strategy consists of optimal primary and secondary well spacings which are decision variables in the influence diagram. Decline parameters provided in terms of probability distributions are the uncertain variables used in calculation of the expected NPV. **Fig. 32** shows a partial decision tree which demonstrates the structure of the sequential development program.

Fig. 31— Influence diagram for the Berland River area development plan decision.

Fig. 32— Partial decision tree for the Berland River area development plan.

The decline curve analysis results indicate that the initial production rates are log-normally distributed (Fig. 29). Therefore, first stage q_i values are transformed to fit a log-normal distribution by using the following equations,

$$mean = e^{\left(\mu + \frac{\sigma^2}{2}\right)}$$

$$std.dev = \left(e^{\sigma^2} - 1\right)^{\frac{1}{2}} \left(e^{2\mu + \sigma^2}\right)^{\frac{1}{2}}$$

The 90th, 50th and 10th percentiles (P90, P50 and P10) are also computed, which represent high, medium and low production rates at Stage 1 and are assigned with probabilities of 25%, 50% and 25%, respectively. These percentiles along with the pairwise correlation coefficients will be used in computing the conditional means and standard deviations of Stage 2 given Stage 1 to construct the joint probability distributions. The following equations are used in this calculation,

$$\mu_{x|y} = \mu_x + \rho \frac{\sigma_x}{\sigma_y} (y - \mu_y)$$

$$\sigma_{x|y}^2 = (1 - \rho^2) \sigma_x^2$$

After specifying the joint probability distribution of q_i over all possible combinations of outcomes, the corresponding cumulative productions are calculated at a discount rate of 10%. Based on the discounted cumulative production and price environment, the expected net present value (NPV) of future cash flows is determined for each scenario.

6.2 Results of the Decision Model

The decision model has been employed in two different price environments (low and high) and results for each scenario are analyzed and compared. **Table 30** shows the low price environment where gas price, marginal costs, fixed costs, drilling cost and discount rate are the major parameters. Based on these values, the decision model calculates the expected NPV for each scenario and selects the one with the highest.

Table 30— Low price environment.

Parameter	Units	Value
Gas Price	\$/MCF	5.50
Marginal Costs	\$/MCF	1.00
Fixed Costs	MM \$/yr/well	0.05
Drilling Cost	MM \$/well	1.00
Discount Rate		0.10

Table 31 shows the decision model results in the low price environment, for stage length of 1 year. Results indicate that if the initial production q_i is high, the downspacing alternative that maximizes NPV is the 160 acre-spacing. This means that, the optimal strategy is to start development on 640 acres and downspace to 160 acres if high production is observed. However, if production is low, continuing development on 640 acres would be the best choice. It is worthwhile to mention that, the dynamic 640-acre strategy is better than the static 160-acre strategy by \$660K (i.e., \$2.09MM - \$1.43MM = \$0.66MM).

Similarly, **Table 32** outlines the decision model results in the low price environment, for stage length of 3 years. It is seen that for the primary stage, development on 640 acres and for the secondary stage downspacing to 160 acres should be selected.

Table 31— Decision model results showing the optimal development plan in low price environment. Stage length is 1 year.

(\$3.27)	0.5	M				(\$3.6)	80	(\$3.6)
	0.25	L				(\$5.5)	80	(\$5.5)

Comparing the results for stage lengths of 1 year and 3 years, it is seen that the expected NPVs for a 3-year stage is lower than a 1-year stage. Regardless, the dynamic (640-acre) strategy is still better than the static (160-acre) strategy (i.e., \$0.72MM - \$0.63MM = \$0.09MM).

Next, the decision model is employed in the high price environment (**Table 33**), for stage length of 1 year. The decision model results indicate that, selecting 640-acre spacing for the primary stage and downspacing to 160-acre is the best option, unless low initial production is observed (**Table 34**).

However, in the high price environment and for a stage length of 3 years, the optimal development strategy is to start development on 160 acre-spacing and not to downspace (**Table 35**).

Table 32— Decision model results showing the optimal development plan in low price environment. Stage length is 3 years.

In this chapter, a practical and flexible framework was presented which fully models the dependence between development stages and decides on the next stage based on the previous stage information. The decision model presented herein provides quick recommendations to operators on development strategies and will prove to be useful in determining an optimal development strategy.

CHAPTER VII

CONCLUSIONS AND RECOMMENDATIONS

7.1 Conclusions

In this work, we developed a probabilistic reservoir model which allows prediction of production profiles under different development scenarios. These production profiles are integrated to a Bayesian decision model and allow calculation of the expected net present value for each scenario. To facilitate the integration of the reservoir and decision models, the simulated production profiles are fit with decline curves and the corresponding decline parameters are determined to serve as inputs to the decision model. The model distinguishes itself from existing technologies, by its speed, cost-effectiveness, ability to model production uncertainty and spatial dependence between wells. The integration of Monte Carlo techniques with reservoir simulations yields random combinations of the uncertain parameters, hence to permit the modeling of reservoir heterogeneity.

A VBA code was developed which allowed thousands of simulations to be performed automatically; thereby providing a full spectrum of production profiles. Incorporation of these production profiles to the decision model rendered a tool that can offer recommendations to operators on selecting the optimal development strategy with the objective of maximizing profitability.

The reservoir and decision modeling tools developed in this project were applied to UGR's tight gas assets in Berland River, Alberta to determine the optimal well spacing in the area. The decision context modeled consisted of 2 development decisions: the primary and secondary well spacings. In particular, the plan is to start development on a specific well spacing (Stage 1) and then decide on whether to downspace or not (Stage 2) based on the primary production results. Also, to understand the trade-off between Stage 1 duration and spacing, results were evaluated for 2 different stage lengths (1- and 3- year).

The decision model was employed in two different price environments: In a low price environment, for both 1 and 3 year-stage lengths, the optimal strategy is 640 acres to start and then downspace to 160 acres if high production is observed. When a higher price environment is considered, for stage length of 1 yr, the optimal strategy is to select 640 acres for primary stage and then downspace to 160 acres unless low production is observed. On the other hand, again in the high price environment but for stage length of 3 yrs, the optimal strategy is to start development on 160-acre spacing and not to downspace. In terms of profitability, in the low price environment, the expected NPVs for a 3-year stage are lower than a 1-year stage; however, the opposite holds for the high price environment.

7.2 Limitations

As with any modeling approach, the method presented in this study is also based on certain approximations. These approximations are the major cause for divergence of the model from the real case. Some limitations of the probabilistic reservoir model developed in this study are as follows: (1) The current single-well approach can model the reservoir heterogeneity to a certain extent but it cannot provide a full representation. (2) Pressure interference between wells cannot be modeled perfectly. (3) While the reservoir model is built based on the assumption that at most 8 wells will be drilled in a section due to lengthy simulation times, only 4 representative wells are modeled. However, modeling all the wells would yield more precise results.

7.3 Recommended Future Work

The reservoir model can be improved to model completion efficiency (stimulation failure) in more detail and the developed tool can be extended to yield the optimal well completion strategy in addition to the primary and secondary optimal well spacings.

The reservoir model can be applied to other fields to confirm and extend functionality. Once the model's applicability on other fields is verified and after further

refinements, the tools and methods developed in this project may be transformed into a fully functional and flexible software module used for determining optimal development strategies for unconventional tight gas reservoirs.

In future research, a multi-well model approach can be investigated to better model the reservoir heterogeneity and the pressure interference between Stage 1 and Stage 2 wells.

NOMENCLATURE

a	= the range beyond which variogram remains essentially constant, m
a_0	= regression coefficient used in the moving window technology
a_1	= regression coefficient used in the moving window technology
a_2	= regression coefficient used in the moving window technology
a_3	= regression coefficient used in the moving window technology
a_C	= main diagonal of coefficient Matrix A, scf . cp/psi ² . D
a_N, a_W	= north and west flow coefficient, scf . cp/psi ² . D
a_E, a_S	= east and south flow coefficient, scf . cp/psi ² . D
A	= well spacing, acre
b	= hyperbolic exponent
B	= formation volume factor, reservoir ft ³ /scf
BY	= best 12 consecutive months of production divided by 12, MSCM/M
c_t	= total system compressibility, psi ⁻¹
C_0	= nugget
C_1	= difference between sill and nugget
C_1	= intermediate result in the reservoir model of moving window technology
C_2	= intermediate result in the reservoir model of moving window technology
C_3	= intermediate result in the reservoir model of moving window technology
$C(h)$	= covariance function
d	= right-side column vector of the 2D flow equation
D	= decline rate, 1/year
Di	= initial decline rate, 1/year
F_{cD}	= dimensionless fracture conductivity
Gp	= cumulative production, standard cubic feet
h	= lag distance between pairs, ft
h	= net pay thickness, ft
J'	= well index

k	= permeability, md
k_{gas}	= gas permeability, md
k_f	= fracture permeability, md
L_f	= fracture length, ft
Np	= cumulative production, MMscf
p	= the vector of well block pressure, psi
p_i	= initial reservoir pressure, psia
p_p	= real-gas pseudopressure, m/Lt^3 , psi^2/cp
p_{wf}	= flowing bottomhole pressure, psi
$p_{pi,j}^n$	= real-gas pseudopressure in (i,j) grid at n time step, m/Lt^3 , psi^2/cp
$p_{pi,j-1}^{n+1}$	= real-gas pseudopressure in (i,j-1) grid at n+1 time step, m/Lt^3 , psi^2/cp
$p_{pi-1,j}^{n+1}$	= real-gas pseudopressure in (i-1,j) grid at n+1 time step, m/Lt^3 , psi^2/cp
$p_{pi,j}^{n+1}$	= real-gas pseudopressure in (i,j) grid at n+1 time step, m/Lt^3 , psi^2/cp
$p_{pi+1,j}^{n+1}$	= real-gas pseudopressure in (i+1,j) grid at n+1 time step, m/Lt^3 , psi^2/cp
$p_{pi,j+1}^{n+1}$	= real-gas pseudopressure in (i,j+1) grid at n+1 time step, m/Lt^3 , psi^2/cp
q	= production rate, Mscf/D
q_i	= initial production rate, Mscf/D
r_o	= equivalent radius of well gridblock, L, ft
r_w	= wellbore radius, L, ft
s	= skin factor, dimensionless
t_o	= transition time, years
T	= temperature, T, °R
T_{sc}	= temperature at standard condition, °R
Δt	= timestep, t, days
V_p	= pore volume of gridblock, L^3 , ft^3
VBV	= virgin best year, MSCM/M
α	= coefficient in the a_C equation
$\rho(h)$	= correlation function

$\gamma(h)$	= semi-variogram
μ	= viscosity, cp
ϕ	= porosity, fraction
w	= fracture width, ft
z	= z factors

Fig. E3— Cumulative distribution plot of q_i for Well 4, stage-length of 1 year: (a) 1 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E4— Cumulative distribution plot of q_i for Well 1, stage-length of 3 years: (a) 3 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E5— Cumulative distribution plot of q_i for Well 2, stage-length of 3 years: (a) 3 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E6— Cumulative distribution plot of q_i for Well 3, stage-length of 3 years: (a) 3 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E7— Cumulative distribution plot of q_i for Well 4, stage-length of 3 years: (a) 3 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E8— Cumulative distribution plot of q_i for Well 1, stage-length of 5 years: (a) 5 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E9— Cumulative distribution plot of q_i for Well 2, stage-length of 5 years: (a) 5 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E10— Cumulative distribution plot of q_i for Well 3, stage-length of 5 years: (a) 5 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

(a)

(b)

Fig. E11— Cumulative distribution plot of q_i for Well 3, stage-length of 5 years: (a) 5 year- q_i (Stage 1), (b) 20 year- q_i (Stage 1 + Stage 2).

VITA

Gulcan Turkarslan was born in Ankara, Turkey in 1985. She received her high school baccalauréat diploma at Le Lycée Tevfik Fikret d'Ankara and graduated as the valedictorian of class of 2003. She continued her studies at the Middle East Technical University (METU), Ankara, and graduated 1st in her class with a Bachelor of Science degree in Petroleum & Natural Gas Engineering. In 2008, she joined the Department of Petroleum Engineering at Texas A&M University, College Station to pursue her Master of Science degree. Her research interests focus on reservoir engineering, reservoir simulation and unconventional resources. In the future, she plans to further develop and apply her skills as a reservoir engineer. She can be reached at her permanent address:

Umit Mahallesi, 2436 Sok. 18/1

Umitkoy, Ankara
